2 **Weighting Schemes**

3 Kenneth C. Land
4 Department of Sociology, Duke University,
5 Durham, NC, USA

Defining individual i 's importance weight 25
(preference, judgment) for domain k as w_{ik} and 26
overall well-being/quality of life (WB/QOL) 27
judgment as Q_i , an algebraic representation of 28
weighted average model (WAM) to predict i 's 29
WB/QOL judgments is 30

6 **Synonyms**

7 **Composite index construction; Subjective**
8 **weighting**

where w_{ik} is individual i 's the weight for the 31
 k th domain and the summation is over the total 32
number of domains used to make judgments of 33
WB/QOL (Hagerty & Land, 2007). 34

9 **Definition**

10 Weighting schemes are systems of weights
11 applied to social indicators or measures of sub-
12 jective well-being used in the construction of
13 composite indices of domains of well-being and
14 overall well-being/quality of life (WB/QOL).
15 Usually, the weights refer to individuals' sub-
16 jective weighting of various domains or aspects of
17 life or to some transformation thereof.

Using similar notation, the *weighted product* 35
model (WPM) can be written as 36

$$Q_i = \prod_k [(x_k)^{w_{ik}}], w_{ik} > 0,$$

where the product is taken over the total number 37
of domains. Note that the weighted average 38
model can be viewed as a logarithmic transfor- 39
mation of the weighted product model. 40

18 **Description**

19 Two major approaches to the conceptualization
20 of alternative weighting schemes are (1) the
21 weighted average model of subjective judgments
22 (Hagerty & Land, 2007) and (2) the weighted
23 product model (Munda & Nardo, 2003; see also
24 Nardo et al., 2005).

Zhou, Ang, and Zhou (2010) developed 41
a multiplicative optimization extension of the 42
WPM by application of Data Envelopment 43
Analysis (DEA)-type methods to determine the 44
values of weights of individual indicators in 45
a composite index such as the life expectancy at 46
birth, education (a normalized index of mean 47
years of schooling of adults aged 25 and expected 48
years of schooling for children of school going 49
age), and Gross National Income per capita indi- 50
cators used to calculate the Human Development 51

52 Index. The DEA method originally was devel-
 53 oped for efficiency analysis in economics and
 54 management science (Charnes, Cooper, Lewin,
 55 & Seiford, 1994; Charnes, Cooper, & Rhodes,
 56 1978; Land, Lovell, & Thore, 1993). It trans-
 57 forms a multiplicative optimization problem
 58 into a series of linear programming problems
 59 (Danzig, 1963) in which weights for composite
 60 scores are determined by internal comparisons of
 61 each of a set of entities with each other with
 62 respect to their efficiency in producing outputs
 63 (e.g., consumer products) from given levels of
 64 inputs (e.g., labor, capital).

[Au1]

65 Zhou et al. (2010) applied DEA to calculate
 66 two sets of weights for the component indicators
 67 of a composite QOL index – a set of “best”
 68 weights for each entity calculated in comparison
 69 to the “best practice” entity or entities on each
 70 specific indicator and a set of “worst” weights
 71 calculated in comparison to the “worst practice”
 72 entity or entities on each specific indicator. They
 73 then calculated composite index scores for each
 74 entity being compared as weighted averages of
 75 logarithmic transformations of the two sets of
 76 weights, and, in the absence of a preference for
 77 one set of weights or the other, suggested equal
 78 weighting as a fairly neutral choice. Zhou et al.
 79 suggested that this extension of the WPM can
 80 provide an alternative to subjectively determined
 81 weights for composite indices. In an empirical
 82 application, Zhou et al. showed that the ranks
 83 of most of 27 countries in the Asia and Pacific
 84 region given by the conventional Human
 85 Development Index remain unchanged when
 86 they are ranked by composite indices based on
 87 the multiplicative optimization method.
